We report a biomarker-based non-endoscopic method for detecting Barrett’s esophagus (BE) based on detecting methylated DNAs retrieved via a swallowable balloon-based esophageal sampling device. BE is the precursor of, and a major recognized risk factor for, developing esophageal adenocarcinoma. Endoscopy, the current standard for BE detection, is not cost-effective for population screening. We performed genome-wide screening to ascertain regions targeted for recurrent aberrant cytosome methylation in BE, identifying high-frequency methylation within the CCNA1 locus. We tested CCNA1 DNA methylation as a BE biomarker in cytology brushings of the distal esophagus from 173 individuals with or without BE. CCNA1 DNA methylation demonstrated an area under the curve of 0.95 for discriminating BE-related metaplasia and neoplasia cases versus normal individuals, performing identically to methylation of VIM DNA, an established BE biomarker. When combined, the resulting two biomarker panel was 95% sensitive and 91% specific. These results were replicated in an independent validation cohort of 149 individuals who were assayed using the same cutoff values for test positivity established in the training population. To progress toward non-endoscopic esophageal screening, we engineered a well-tolerated, swallowable, encapsulated balloon device able to selectively sample the distal esophagus within 5 min. In balloon samples from 86 individuals, tests of CCNA1 plus VIM DNA methylation detected BE metaplasia with 90.3% sensitivity and 91.7% specificity. Combining the balloon sampling device with molecular assays of CCNA1 plus VIM DNA methylation enables an efficient, well-tolerated, sensitive, and specific method of screening at-risk populations for BE.

INTRODUCTION

The incidence of esophageal adenocarcinoma (EAC) has more than quadrupled in the past 30 years (1–4), and the prognosis for EAC patients remains poor, with a less than 20% survival at 5 years (4, 5). Barrett’s esophagus (BE), a premalignant intestinal-type columnar metaplasia that replaces the normal squamous mucosa of the distal esophagus, is the only known precursor for EAC, but its detection currently requires performing esophagogastroduodenoscopy (EGD). Because of the high cost of EGD and the lack of a randomized controlled trial demonstrating cost-effective reduction in EAC, endoscopy screening for BE has not been routinely recommended (6, 7).

Thus, in about 95% of cases of EAC, the presence of the antecedent BE remains undetected and unknown (8). Hence, there is a need for additional methods for BE detection that are less expensive than EGD and can be widely and readily implemented in an at-risk population. Molecular biomarkers for detecting BE are potentially valuable in this regard.

Acquisition of aberrant cytosome methylation within CpG-rich genomic islands is a common accompaniment of many cancers and can serve as a neoplasia biomarker (9–13). We have previously reported that de novo DNA methylation of the CpG island overlapping the first exon of the vimentin gene (mVIM) is a highly sensitive BE biomarker that is present in biopsies of about 90% of BE patients, suggesting utility of mVIM as a potential biomarker for BE screening (14). In an initial pilot study, we further found that mVIM could be detected in esophageal brushings, suggesting that mVIM can serve as a molecular cytology biomarker to enable non-endoscopic detection of BE (14). Reduced representation bisulfite sequencing (RRBS) is a whole-genome approach that allows for unbiased assessment of DNA methylation within CpG-dense regions of the human genome, which encompass most promoters and other regulatory regions (15, 16). RRBS thus provides the potential to identify an extended biomarker panel with increased effectiveness for detecting BE. The aims of this study were hence to identify methylated DNA biomarkers of esophageal neoplasia, to define the sensitivity and specificity of such markers in comparison to and/or in combination with mVIM for detecting BE metaplasias and related neoplasias, and to further test the efficacy of these biomarkers for detecting BE in samples obtained via a non-endoscopic swallowable balloon-based esophageal sampling device as compared to samples obtained via endoscopy-directed brushings.
RESULTS

RRBS discovery of DNA methylation biomarkers of esophageal neoplasia

We performed RRBS analysis on a set of 26 esophageal cancer (EAC) biopsies and their respective matched normal squamous biopsies, 15 biopsy or brushing samples of BE, and 5 esophageal cancer cell lines (fig. S1). Of 3,091,193 analyzable CpGs, 26,601 CpGs showed methylation below 10% in all the informative normal squamous samples (requiring at least four informative normal samples, each having a sequencing depth of at least 20×). When compared in BE, 1970 of these CpGs showed >30% methylation in at least four samples comprising 45% or more of informative cases (all having a sequencing depth of >10×). Of these 1970 CpGs methylated in BE, 1011 CpGs additionally demonstrated >30% methylation in at least eight informative EAC biopsies (all having a sequencing depth of >10×). These 1011 CpGs that were differentially methylated between normal squamous versus BE and EAC samples were clustered into 412 differentially methylated CpG patches, defined as clusters of differentially methylated CpGs each less than 200 base pairs (bp) apart. The best 26 of these patches were selected for further inspection (table S1). Of these, the best candidate for discriminating BE-related lesions from normal esophagus was a patch of seven CpGs located on chromosome 13, in the CpG island spanning the promoter and 5’ untranslated region of CCNA1 (Fig. 1A). Seventy percent of the BEs characterized by RRBS showed average methylation exceeding 30% across this patch (Fig. 1B). Moreover, all three informative esophageal cancer cell lines showed nearly 100% methylation across this patch, suggesting that both CCNA1 alleles were densely methylated and that the methylation signal in the biopsies was derived from the abnormal Barrett’s epithelial cells (Fig. 1B).

CCNA1 and VIM DNA methylation in esophageal biopsies

To further interrogate the CCNA1-associated DNA methylation patch, we designed a next-generation sequencing (NGS)–based assay for targeted resequencing of this differentially methylated region (Fig. 1A). We targeted a cluster of 21 consecutive CpG residues that overlap with the methylated patch identified by RRBS (Fig. 1A). The NGS approach allows for determining the methylation status for each of these 21 CpGs across a single individual DNA read and thereby calculating the percent of CpG methylation present across this region for each individual CCNA1 locus DNA molecule, thus enabling each DNA read to be classified as “methylated” versus “unmethylated.” This approach further provides a metric of tissue methylation, corresponding to the percent of all the individual CCNA1 DNA molecules identified as methylated (percent of CCNA1 “methylated reads”), that can further be referenced as exceeding or not exceeding the upper limit of the normal range. This patch-based algorithm suppresses background from random methylation of individual CpGs and provides enhanced discrimination of normal versus diseased tissue (fig. S2).

We used this method to characterize an expanded set of esophageal biopsies (fig. S1) and to compare the performance of DNA methylation at the CCNA1 versus VIM loci, reflecting our previous identification of VIM region methylation as a high-performance biomarker of esophageal neoplasia (14). CCNA1 locus methylation (mCCNA1) was significantly increased in all BE-related lesions versus normal (P < 0.001; Fig. 2A), with mCCNA1 detected in 81% percent of nondysplastic BE (NDBE), 68% percent of BE with high-grade dysplasia (HGD), and 90% percent of EAC but in only 1% of normal squamous samples (classifying a tissue as methylated if it had >10% of methylated CCNA1 reads and classifying a CCNA1 read as methylated when methylation was detected at ≥16 of 21 target CpG positions). These results were similar to those obtained by bisulfite sequencing analysis of these samples for VIM locus methylation (mVIM; Fig. 2B), in which >10% methylation was demonstrated by 100% of NDBE, 63% percent of BE with HGD, and 76.5% percent of EAC but by only 1% of normal squamous samples (classifying VIM reads as methylated when methylated at ≥8 of 10 target CpG positions).

CCNA1 and VIM DNA methylation for detecting BE and EAC in cytology brushings

To model a “molecular cytology” assay for detecting BE, we used the NGS bisulfite sequencing assay to measure CCNA1 DNA methylation (mCCNA1) in a training set of esophageal cytology brushings (fig. S1). Brushings of the gastroesophageal (GE) junction were obtained from 62 control subjects with or without symptomatic GE reflux esophagitis (n = 8). Brushings were also obtained from 111 patients including 62 individuals with cancer, either EAC (n = 48) or GE junction...
adenocarcinoma (n = 14), and 49 individuals with BE. Of BE cases, 12 had nondysplastic short-segment BE (SSBE; < 3 cm), 19 had nondysplastic long-segment BE (LSBE; ≥3 cm), 8 had low-grade dysplasia (LGD), and 10 had HGD. Eighty-three percent of study participants were white. The disease group was older than controls (P < 0.0001) and included more males, reflecting the epidemiology of BE. There was no significant difference in the prevalence of smoking between cases and controls (table S2).

Figure 3A shows the receiver operating characteristic (ROC) curve for mCCNA1 in these training set samples, in which the assay demonstrated an area under the curve (AUC) of 0.95. An optimal cutoff, in which a sample was detected as positive if it had >3.12% methylated CCNA1 templates, maximized the sum of sensitivity plus specificity. At this cutoff, mCCNA1 demonstrated 90.7% sensitivity for detecting BE or cancer with 98.4% specificity. As a comparator, Fig. 3B shows the ROC curve for the same samples assayed for mVIM by bisulfite sequencing analysis. Similar to mCCNA1, the mVIM assay showed an AUC of 0.95. The optimal cutoff for this assay, of 1.05% mVIM content, provided a sensitivity of 90.7% and a specificity of 93.2% (Fig. 3B). These mVIM results are consistent with our previous observation in a pilot set of 34 esophageal brushings that were analyzed for mVIM by quantitative methylation-specific (qMS)–polymerase chain reaction (PCR) (14).

To validate the performance of mCCNA1 and mVIM in molecular cytology applications, we examined a second independent set of esophageal cytology brushings from 149 new individuals recruited at five different cancer centers across the United States (fig. S1). These individuals included 30 controls with normal esophageal morphology and 119 cases with BE or cancer (table S2). Similarly to the training set, and reflecting the biology of BE, participants in the validation set were 93% white. Training and validation populations did not significantly differ by gender or smoking history, but controls were older in the validation than in the training set (table S2). As shown in Fig. 3 (C and D), the validation population again showed an AUC of 0.95 for mCCNA1 and 0.96 for mVIM. Moreover, sensitivity and specificity of mCCNA1 and mVIM in the validation population replicated those of the training population, using the same cutoffs for test positivity as prespecified by the training data set (Fig. 3, C and D versus A and B, and table S3).

BE progresses from nondysplastic metaplasias to LGD and then HGD that ultimately give rise to EAC (17, 18). Given the equivalent

**Fig. 2.** NGS bisulfite sequencing assay of DNA methylation in esophageal biopsies. (A) CCNA1 locus methylation (mCCNA1) in esophageal neoplasia and control patients. N Sq, normal squamous biopsies; NDBE, nondysplastic BE; HGD, BE with high-grade dysplasia. Fraction of methylated reads in each sample is indicated on the y axis. P < 0.001 for one-way analysis of variance (ANOVA) comparison and P < 0.001 for post hoc Student-Newman-Keuls test of N Sq versus BE, HGD, and EAC. (B) VIM locus methylation (mVIM) in esophageal neoplasia and control patients. Fraction of methylated reads in each sample is indicated on the y axis. P < 0.001 for one-way ANOVA comparison and P < 0.001 for post hoc Student-Newman-Keuls test of N Sq versus BE, HGD, and EAC.

**Fig. 3.** ROC curves of mCCNA1 and mVIM assayed in esophageal cytology brushings from control normal-appearing GE junctions versus BE and EAC cases. (A and B) Training samples. (A) mCCNA1, n = 61 controls and 108 cases. (B) mVIM, n = 59 controls and 107 cases. (C and D) Validation samples. (C) mCCNA1, n = 28 controls and 115 cases. (D) mVIM, n = 27 controls and 117 cases. Area under the curve (AUC) and the sensitivity and specificity of the assays at the indicated cutpoint are listed for each graph, with the cutoffpoint value of percent methylation that defines a positive test denoted by “At >.”
performance of mVIM and mCCNA1 in the training and validation populations, we performed a pooled analysis to examine these markers’ performance at each of the stages of progression of BE-related neoplasia. As shown in Table 1, mCCNA1 and mVIM markers were both highly sensitive for detecting each of the stages of BE-related disease, including early NDBE metaplasias, dysplasias (LGD and HGD), and cancers. mVIM performed better than mCCNA1 in detecting NDBE (91.5% versus 79.7%), whereas mCCNA1 showed a slightly higher sensitivity for dysplastic BE (94.5% versus 91.1%) and cancer (94.9% versus 90.7%). When considered in combination, mVIM and mCCNA1 jointly detected 92% of NDBE, 96% of dysplastic BE, and 96% of cancers while maintaining specificity above 90% for negatively classifying brushings from the normal GE junction (Table 1). The combination of mVIM and mCCNA1 was more sensitive than either marker individually, even when the specificity of each individual marker was adjusted to match that of the combination (table S4).

Smoking-induced methylation in the upper esophagus

Esophageal brushings under endoscopic guidance provided for directed sampling of the distal esophagus. However, certain non-endoscopic approaches to esophageal sampling, for example, using sponge-based devices, require sampling the entire esophagus. To simulate this process, we obtained additional cytology brushings of the proximal normal squamous esophagus from all participants in our training population. Smoking-induced methylation in the proximal esophagus came from noting that the great majority of methylation-positive samples were obtained from current or former smokers, with smokers accounting for 75% of samples testing mVIM-positive (P = 0.0155) and 100% of samples testing mCCNA1-positive (P = 0.0094). Further review determined that most of the methylation-positive normal squamous biopsies from our initial experiments (Fig. 2) also came from smokers, although the numbers were too few to support statistical analyses. These findings suggest that using methylated DNA markers for non-endoscopic detection of BE will be enhanced by device designs that allow for selective sampling of the distal esophagus and for protection of samples from contamination by the proximal esophagus. Reassuringly, for such a selective sampling approach, reanalysis of brushings from the distal esophagus showed smoking to have no significant effect on the extent of VIM and of CCNA1 methylation detectable in either the normal GE junction of control individuals or in cases with BE or Barrett’s related neoplasia (table S5).

Detecting BE and EAC via non-endoscopic balloon sampling

To enable non-endoscopic targeted sampling of the distal esophagus, we designed and built an encapsulated, inflatable, surface-textured balloon. The device is swallowed in a pill-sized 16 × 9-mm capsule attached to a thin 2.16-mm silicone catheter (Fig. 5, A and B). After delivery to the stomach, the balloon is inflated by injecting 5 cm³ of air through the catheter (Fig. 5C) and then gently withdrawn 3 to 6 cm back through the distal esophagus to sample the luminal epithelial surface. The balloon is then deﬂated and inverted back into the capsule (Fig. 5D), thus protecting the acquired biosample from further dilution or contamination in the proximal esophagus and the oropharynx. After retrieval of the capsule through the mouth, DNA is extracted from the balloon surface for molecular analysis.

One hundred ﬁfty-six patients underwent unsedated distal esophageal sampling with the balloon device before scheduled EGD. Most of the participants were male (71%) and white (83%), with an average age of 64.1 years (SD = 12.5 years). Twenty-eight (18%) were unable to swallow the device. However, the 128 successful participants in trial reported little to no anxiety, pain, or choking and only low to intermediate gagging (table S6). On average, the balloon reached the stomach in 3.3 min (range, 1.0 to 7.7 min) with excellent tolerance in 72% of cases (table S6). Ninety-three percent of individuals who participated

---

Table 1. mVIM and mCCNA1 performance in the combined set of all distal esophagus brushings. VIM and CCNA1 gene methylation was assayed in DNA samples from cytology brushings of the distal esophagus from the following: unaffected controls brushed at the gastroesophageal junction (control GEJ); cases of NDBE, further subclassified as short-segment BE (SSBE) of 1 to 3 cm or long-segment BE (LSBE) of ≥3 cm; BE with low-grade dysplasia (LGD); BE with HGD; EAC (including junctional cancer of the esophagus). Samples were scored as VIM-methylated for mVIM >1.05% and as CCNA1-methylated for mCCNA1 >3.12% (using receiver operating characteristic [ROC] defined cutoffs from Fig. 3, A and B). Cases were positive for the panel of mCCNA1 plus mVIM if either marker tested positive. Controls were negative for the panel when both mCCNA1 and mVIM were negative. Controls with one negative marker and one marker with assay failure were excluded. Entries indicate percent sensitivity or speciﬁcity (%) and total number of individuals tested (n).

in esophageal balloon testing would repeat the procedure if necessary, whereas 95% would recommend it to others (table S6).

From the 128 balloons processed, an adequate DNA amount of at least 60 ng was obtained in 116 instances (91%). Thirty individuals were additionally excluded from further analysis because of either having a history of previous esophageal ablation for Barrett’s dysplasia (n = 23), having gastric intestinal metaplasia (IM; n = 4), or having esophageal IM of <1 cm in length (ultrashort BE; n = 3). The 86 evaluable individuals (table S7) included 36 controls free of IM but with erosive esophagitis (n = 3) or other indications for upper endoscopy (n = 33). The evaluable individuals also included 50 cases, 42 with BE (31 nondysplastic, 6 LGD, 4 HGD, and 1 indefinite for dysplasia) and 8 with EAC or junctional cancers (Table 2). In these balloon samples, mVIM and mCCNA1 discriminated cases and controls with performance nearly identical to that found in the cytology brushing samples, with ROC curves for balloon samples demonstrating an AUC of 0.92 for mCCNA1 and 0.91 for mVIM (Figs. 6A versus 3A and 6B versus 3B). Balloon samples of the normal GE junction showed less background methylation of CCNA1 than did cytology brushings, and at a cutoffpoint of 1% for mCCNA1, the assay detected 72% of cases while retaining 100% specificity (Table 2). mVIM demonstrated essentially the same cutoff point in balloon samples (1%) as in cytology brushings, and the mVIM assay detected 80% of cases with a specificity of 91.7% (Table 2). When the two markers were jointly applied to the balloon samples, the panel detected 90.3% of NDBE cases with a specificity of 91.7% (Table 2). The combination included a slightly higher sensitivity of 94.4% for detecting LSBE (≥3 cm) but still detected SSBE of 1- to 3-cm length with 84.6% sensitivity. Although the study included only a few cases of dysplasia or cancer, the combination of mVIM and mCCNA1 did detect 9 of 11 dysplasias and seven of eight cancers, yielding a sensitivity of 88% for detection of all BE, dysplasias, and cancers studied (Table 2). Overall, the encapsulated balloon device successfully sampled the distal esophagus with excellent tolerability and acceptability and, when combined with bisulfite sequencing for mVIM plus mCCNA1, demonstrated high sensitivity and specificity for detecting BE.

**Methylation in other upper gastrointestinal tract pathologies**

To identify potential confounding sources of VIM and CCNA1 DNA methylation, we performed a retrospective analysis of archival formalin-fixed paraffin-embedded (FFPE) esophageal and gastric specimens that captured common pathologies of the upper gastrointestinal (GI) tract (Table 3). As expected, FFPE biopsies of BE were highly methylated, with 90% testing positive for mVIM, 75% testing positive for mCCNA1, and 90% testing positive for the two-marker panel. Clinical criteria for BE require identifying 1 cm or more of esophageal IM. However, the two-marker panel additionally detected 80% of early esophageal IMs, identifying 80% of IM lesions <1 cm and still confined to the endoscopic GE junction (70% positive for mVIM and 67% positive for mCCNA1). Moreover, among individuals with BE, mVIM or mCCNA1 methylation could also be detected in 30% of biopsy samples of columnar mucosa that had no histologic IM (regions of gastric metaplasia; Table 3), suggesting that the IM in these BE cases arose in an antecedent field of methylation-positive columnar cells. In contrast, among individuals without BE or IM, assays for mVIM and for mCCNA1 were negative in all GE junction samples (n = 55), which included 15 cases with chronic carditis typified by columnar mucosa without IM (Table 3), and methylation was additionally negative in all distal esophagus samples (n = 24). Together, these findings suggest that aberrant methylation occurs at the earliest stages of BE development, in those columnar mucosa that are actively evolving toward IM. Methylation is not simply a consequence of inflammation, because mVIM and mCCNA1 tests were all negative in each of 15 cases of eosinophilic esophagitis, as well as in the aforementioned chronic carditis samples. Methylation was, however, additionally detected in a subset of gastric IM lesions, 22% of which were positive for at least one of the two markers. Moreover, 2 of 13 individuals with *Helicobacter pylori* gastritis, who were at increased risk for but did not have gastric IM, were also positive for VIM or CCNA1 methylation. However, 24 normal gastric fundic mucosa without IM were negative for mVIM in all samples and negative for mCCNA1 in all but one sample. Positive tests for mVIM and mCCNA1 are thus highly associated with IM, predominantly IM of the esophagus but sometimes IM of the stomach.

Consistent with the predictions from this FFPE archive, positive methylation was detected on two of three balloon samples from cases of ultrashort BE (<1 cm), which were unavailable in the primary analysis (two positive for mVIM and none for mCCNA1). Similarly, positive methylation was detected in balloon samples from four of four cases of gastric IM that were also unavailable for the primary analysis (four positive for mVIM and two for mCCNA1). This finding of DNA methylation markers that are shared between gastric metaplasias and very early esophageal metaplasias is consistent with other genomic and cell biology lines of evidence that also point to a common origin between EACs and intestinal-type gastric cancers (19, 20).
VIM methylation was additionally identifiable in esophageal balloon samples from certain individuals in whom dysplastic BE had been previously ablated. Specifically, analysis of balloon samples from 23 endoscopically normal individuals who were unevaluable for the primary study, because of their having had ablation of previous dysplastic BE lesions, also demonstrated positive mVIM signals present in eight (35%) patients (P < 0.017 for increased mVIM positivity in post-ablation versus evaluable control individuals; table S8). This finding suggests that the endoscopically normal post-ablation GE junction, and/or post-ablation neosquamous epithelium, may retain molecular abnormalities associated with previous IM and may hence harbor continued cellular precursors of BE. It will be intriguing to determine whether, on longitudinal follow-up, these individuals who retain VIM methylation after BE ablation will demonstrate a higher risk for BE recurrence. Curiously, only 2 of these 23 post-ablation individuals were positive for CCNA1 methylation.

Biological implications
These studies in the esophagus help to inform the larger understanding of the genesis of aberrant DNA methylation in human neoplasias. Our data strongly point to epithelial cells as the source of both VIM and CCNA1 methylation signals. First, VIM and CCNA1 methylation were both detected in epithelial fractions from microdissected FFPE samples of early and late BE lesions (Table 3). Second, EAC cell lines demonstrated nearly complete biallelic methylation (>97% of alleles methylated) in five of five cell lines for CCNA1 and in four of five cell lines for VIM (fig. S3). Third, testing in whole-organ gastroesophageal porcine explants showed that the balloon device samples a nearly exclusively epithelial cell population (fig. S4). Consistent with this, no breaches of the surface epithelium (no abrasions) were detected in the human participants in this study, all of whom underwent upper endoscopic examination immediately after the balloon procedure. The basis for the aberrant methylation of VIM and CCNA1 genomic loci that we commonly found in BE-related lesions remains obscure. As noted above, smoking was associated with increased mVIM and mCCNA1 only in the proximal (upper) but not in the distal esophagus (fig. 4 and table S5). Moreover, there is no clear functional implication of CCNA1 methylation in BE, because expression of this cyclin family gene is normally restricted primarily to the testis, with lesser expression in the brain, and because CCNA1 expression is not present in either unmethylated normal squamous esophagus or methylated EAC cells (fig. S3). Similarly, VIM expression is also absent in the unmethylated normal squamous esophagus (fig. S3). However, VIM expression is associated with epithelial to mesenchymal transition (EMT) of cancer cells (21), and although VIM expression was absent in all four VIM-methylated EAC cell lines, VIM expression was detected in unmethylated FLO1 EAC cells (fig. S3), suggesting that VIM methylation may provide a mechanism for cancer cells to suppress EMT.

Table 2. mVIM and mCCNA1 performance in esophageal balloon samples. VIM and CCNA1 gene methylation was assayed in DNA samples from non-endoscopic balloon sampling of the distal esophagus from unaffected controls (individuals with gastroesophageal reflux disease (GERD), erosive esophagitis, or no pathology detected during endoscopy); cases of NBDE, further subclassified as SSBE of 1 to 3 cm or LSBE of ≥3 cm; BE with LGD; BE with HGD; EAC (including junctional cancer of the esophagus). Samples were scored as VIM-methylated for mVIM >1.0% and as CCNA1-methylated for mCCNA1 >1.0% (using ROC-defined cutoffs from Fig.6). Samples were positive for the panel of mCCNA1 plus mVIM if either marker tested positive. Entries indicate percent sensitivity or specificity (%) and total number of individuals tested (n). We note that only four HGDs were studied, and in this small sample size, differences in the rate of mVIM and mCCNA1 detection of HGD versus detection of NBDE or EAC are not statistically significant (P > 0.088 for any between group comparisons).

### DISCUSSION

This study demonstrates the feasibility of non-endoscopic office-based molecular cytology screening for BE and EAC. First, we have identified cytosine methylation of the CCNA1 locus as a methylation marker of BE. Second, we have shown that molecular cytology assays of distal esophageal brushings, by bisulfite sequencing detection of the two-marker panel of mVIM and mCCNA1 DNAs, detect BE and EAC with sensitivity and specificity both greater than 90%. Third, we have shown that a swallowable balloon device can obtain DNA samples from the distal esophagus in a rapid simple unsedated outpatient examination and, when combined with bisulfite sequencing for detecting DNA methylation, maintains both sensitivity and specificity for detecting BE and EAC at close to 90%. The combination of this sampling device and molecular diagnostic assay demonstrates the feasibility of non-endoscopic molecular cytology screening for BE as a method for ultimately preventing EAC development.

EAC has steadily increased in incidence over recent decades. With an 82% 5-year mortality rate, this cancer is the most rapidly increasing cause of cancer mortality from solid tumors in the American population (5). BE is a precursor lesion from which EAC develops, and ablation of BE with HGD and/or LGD is recommended to prevent EAC (22, 23). However, the great majority of EACs are diagnosed in patients who have never had previous BE screening. This reflects that most patients with GERD symptoms do not undergo upper endoscopy and, moreover, that 40% of EACs develop in patients with no previous symptoms (24, 25). Thus, the success of ablation approaches in preventing EAC will remain limited without an acceptable and cost-effective method to effectively screen at-risk populations and detect those individuals who are harboring BE. Non-endoscopic balloon sampling paired with molecular assay for mVIM and mCCNA1 offers a technology to address this need for simple noninvasive BE screening.

Given the need, other investigators have also advanced alternative approaches for BE screening. One such approach uses sponge-based devices for esophageal sampling (26, 27). One advantage of the balloon device is that it deploys rapidly by inflation, eliminating the waiting time for the coating on typical sponge devices to dissolve. In addition, as the balloon retracts into its capsule after sampling, it enables directed sampling of the distal esophagus and provides protection of the sample from dilution or contamination from the proximal esophagus or oral cavity. Moreover, the smaller dimensions of the retracted balloon provide for easier and more comfortable retrieval. Balloon sampling of the esophagus was first demonstrated by Falk and colleagues (28), with the current balloon-based device now incorporating additional design enhancements that include optimized surface texturing and the addition of a protective capsule for delivery and retrieval.

Immunohistochemical detection of trefoil factor 3 has also been proposed as a biomarker for detection of BE, with a reported sensitivity of 79.9% when used with a cytospin collection device (29). Attractions of DNA-based biomarkers include absence of subjectivity in interpretation and ease of automation for processing large sample numbers. Although direct comparison between the approaches will be of interest, the finding of 91% sensitivity for detecting BE metaplasia by mVIM plus mCCNA1 assays performed on balloon samples suggests that this approach is likely at least as robust and may offer easier of examination and easier scalability to large populations. The lower background of CCNA1 methylation in control individuals sampled by esophageal balloons, as compared to cytology brushings, is intriguing and perhaps reflects a useful advantage arising from the somewhat more superficial cell layer sampled by the balloon versus by cytology brushings.

We note that this study does have some limitations. The balloon device investigation was conducted at a single tertiary care institution, and establishing generality will require replication at other centers and in community-based populations. Our study population is also predominantly male Caucasians, suggesting caution in extrapolating these results to females and other ethnic groups, in which BE is less

---

Table 3. mVIM and mCCNA1 detection in FFPE biopsies of upper gastrointestinal tract pathologies. mVIM and mCCNA1 were assayed in microdissected formalin-fixed paraffin-embedded (FFPE) biopsies that captured each of the histologies shown. IM, intestinal metaplasia. Samples were scored as methylated for mVIM >1.05% and mCCNA1 >3.12% (the cutpoints established in ROC analysis of esophageal brushings assayed for each marker). Samples were positive for the panel of mCCNA1 plus mVIM if either marker tested positive. Entries indicate percent positive samples (%) and total number of individuals tested (n).

common. In addition, we suffered failures of some participants to swallow the balloon device or of the device to obtain adequate sample. Remedying this limitation will need to be a focus of future enhancements to the device design. Last, we lack longitudinal follow-up to be able to interpret implications of finding positive tests for mVIM and mCCNA1 in endoscopically normal individuals without IM of stomach or esophagus or in higher-risk individuals who are post ablation of dysplastic BE.

In summary, this study suggests that the combination of a balloon-based sampling device with bisulfite sequencing of the VIM and CCNA1 loci provides a highly sensitive and specific yet minimally invasive screening procedure that could be clinically useful for detection and screening of BE.

**MATERIALS AND METHODS**

**Study design**

The study protocol was approved by University Hospitals Cleveland Medical Center and Cleveland Clinic Institutional Review Boards for Human Subject Investigation. Clinical trial registration numbers at ClinicalTrials.gov are NCT02451124 for the non-endoscopic balloon trial and NCT00288119 for the endoscopic cytology brushings study. Subjects referred for outpatient EGD were approached for study participation. Consent for obtaining esophageal brushings and biopsies for research was obtained from subjects before their EGD. Cases were classified as subjects with newly diagnosed BE, those undergoing surveillance of BE, or those with a new diagnosis of esophageal or GE junctional adenocarcinoma undergoing an endoscopic procedure. BE was defined according to current American College of Gastroenterology guidelines as at least 1 cm of endoscopically visible columnar mucosa in the distal esophagus with IM confirmed on histology (7). Lesions <1 cm were classified as ultrashort BE and analyzed separately. Control subjects had no endoscopic evidence of BE and no histological evidence of IM if a clinical biopsy was obtained from either the distal esophagus or GE junction.

The overall study was a nonrandomized observational study. Esophageal brushings were first used to validate findings from esophageal biopsies of methylated vimentin and CCNA1 as biomarkers for detection of BE. Balloon-based esophageal samples were then obtained as a second validation sample. Study size was not prespecified, and results are reported for esophageal brushing samples accrued from June 2011 to February 2017 and for all balloon samples accrued from July 2015 to August 2016. No subjects were excluded from reporting. The primary endpoint of detection of BE and related progressed lesions was prespecified before study initiation. All laboratory samples were assayed by investigators blinded to the clinical status of the subjects.

**Reduced representation bisulfite sequencing**

RRBS was performed as previously described (15). Genomic DNA isolated from frozen esophageal biopsies or cell lines was digested with Msp I (New England Biolabs, no. R0106T). End repair, A-tailing, and adapter ligation were carried out using the NEXTFlex Bisulfite-Seq library prep kit (Bioo Scientific, cat. no. NOVA-5119-02) with additional use of methylated NEXTFlex bisulfite sequencing barcoded adapters (Bioo Scientific, cat. no. NOVA-511912) to allow for multiplexing multiple samples on a single sequencing lane. After adapter ligation, the library was size-fractionated on an agarose gel, and DNA fragments between 170 and 350 bp (corresponding to the initial unligated 40- to 220-bp Msp I digest fragments) were isolated and purified from the gel using Macherey-Nagel gel extraction and PCR purification kit (cat. no. 740609.250). After elution from the columns, DNA was bisulfite-converted using the EpicTect Bisulfite Conversion Kit (QIAGEN, cat. no. 59104). Adapter-ligated and converted libraries were then PCR-amplified and purified using Macherey-Nagel gel extraction and PCR purification kit.

Sequencing was performed on an Illumina HiSeq 2500 using paired-end 100-bp reads. Individual BAM files for each sample were generated for alignment. DNA sequencing reads from each RRBS experiment were aligned to bisulfite-converted and unconverted versions of the human reference genome (hg18) using Bowtie2, and percent methylation for each CpG was calculated by dividing the number of methylated Cs by the total coverage of that base. These analyses were facilitated by the Bismark software (30), which was specifically developed for processing RRBS data. The overall pipeline converts raw RRBS FASTQ files to tables of read depth and percent methylation at each individual CpG site for each individual sample.

**Endoscopic sampling**

During the endoscopy, one cytology brushing (US Endoscopy) was obtained from the proximal squamous esophagus, 20 to 25 cm from the incisors, as soon as the esophagus was intubated. The second cytology brushing was obtained from endoscopic BE or cancer lesions. In endoscopic normal controls, the GE junction was brushed to sample the glandular mucosa as well as distal squamous mucosa. Standard-care clinical biopsies were obtained from suspected BE and cancer cases. Data were collected from subjects regarding demographics, indications for EGD, GERD symptoms, exposures, and past medical history. All diagnoses (Table 1) were established by endoscopic report and histopathology review of clinical biopsy samples. Demographic data for all patients are provided in table S2. Brushes were immediately clipped with wire cutters into empty nuclease-free 0.5-ml cryo-safe tubes and immediately snap-frozen on dry ice for transport to storage at −80°C until use. Genomic DNA was extracted from endoscopic brushes using the DNeasy Blood and Tissue Kit (QIAGEN, cat. no. 69504). The protocol for the purification of total DNA from animal tissues (Spin-Column Protocol) was used with the modification of increasing the digestion time to overnight. Final elution volume was 100 μl. DNA yields from clinical samples were quantitated using the Qubit fluorometer (Invitrogen).

**FFPE tissues specimens**

Archival normal and neoplastic tissue specimens were obtained from the Department of Pathology at University Hospitals Cleveland Medical Center under a tissue procurement protocol approved by University Hospitals Cleveland Medical Center Institutional Review Board. Before use, diagnostic slides of all samples were reviewed by a gastrointestinal pathologist (J.E.W.) for confirmation of the recorded diagnoses. After confirmation of diagnoses, specimens for this study were prepared via punch biopsies of tissue blocks. The presence of IM in designated esophageal biopsies was required for a diagnosis of BE according to published guidelines (7).

DNA was purified using QIAamp DNA Micro Kit (QIAGEN) according to the manufacturer’s protocol with the following modifications: The starting extraction volume was increased to 200 μl of ATL buffer and 50 μl of proteinase K. The cores were digested for 4 days at 60°C. An additional 6 μl of proteinase K was added on days 2 and 3 of incubation. The DNA was eluted from columns in 100 μl of low–tris-EDTA (TE) elution buffer and used immediately for bisulfite conversion or frozen at −80°C until use.

Non-endoscopic esophageal brushing via a balloon device

We designed an encapsulated, inflatable, surface-featured balloon for targeted sampling of the distal esophagus. The device was delivered in a 16 × 9-mm capsule that also protected the acquired biospecimen from potential contamination with proximal esophageal material during withdrawal. Subjects referred for outpatient EGD were approached for study participation. Patients underwent unsedated distal esophageal withdrawal. Subjects referred for outpatient EGD were approached for study participation. The device was delivered via a balloon that also protected the acquired biospecimen for targeted sampling of the distal esophagus. The device was delivered via a balloon, which was then inflated, cut off from the capsule, and immediately frozen. DNA was extracted from balloons using the same protocol as for endoscopic brushings but with the modification of increasing the volumes of kit buffers ATL and AL to 1 ml, to completely cover the balloons. After the procedure, each patient filled out a standardized tolerance and acceptance questionnaire (table S9) (31).

Bisulfite conversion of the genomic DNA

To create a template for PCR and then DNA methylation analysis, DNA samples were subjected to treatment with sodium bisulfite, which converts unmethylated cytosine bases into uracil, while leaving methylated cytosines intact, using an Epitect kit (Qiagen) according to the manufacturer’s protocol. The person performing the methylation analysis was blinded to the clinical history of the samples until after all procedures and calculations were completed.

Bisulfite sequencing–based methylation detection

Bisulfite-converted DNA samples from cytology brushings were analyzed by NGS. Bisulfite-specific, methylation-indifferent PCR primers were constructed as a mixture of primers against converted products of fully methylated or fully unmethylated templates and were used to amplify a differentially methylated region of the vimentin exon 1 CpG island (previously described, (32)) or CCNA1 (table S10). Platinum Taq reaction mix (Invitrogen) was supplemented with 1 mM MgCl₂, 0.2 mM deoxyribonucleotide triphosphates (New England Biolabs), 0.5 M betaine (Sigma), and a mix of the four primers, each at 0.1 μM final concentration. PCR was performed using a touchdown protocol, where after the activation of Taq polymerase at 95°C for 5 min, the initial cycling conditions were 95°C for 45 s, 65°C for 45 s, and 72°C for 45 s. The annealing temperature was decreased by 3°C every three cycles to a final of 55°C. An additional 33 cycles of PCR were performed for the annealing temperature of 55°C. Successful amplification was confirmed by agarose gel electrophoresis. PCR products were purified using NucleoSpin Gel and PCR Clean-up Kit (Macherey-Nagel) and quantitated by Qubit. The NextFlex Rapid DNA-Seq Kit (Bio Scientific) was used to prepare indexed libraries for NGS sequencing (Illumina-compatible), and NGS was performed using a MiSeq platform at the McGill University and Génomique Québec Innovation Centre, Montréal, Canada. FFPE DNA samples were bisulfite-converted and sequenced by Epipert (Zymo Research), using the same protocol as above.

Analysis of non-endoscopic balloon DNA samples was done the same way as for brushing samples above, except that the PCR amplification primers (table S10) were indexed by adding 96 different 7-bp index tags to the 5′ end of both forward and reverse primers (table S11). The amplification with indexed primers was carried out under the same conditions as for nonindexed primers, and the PCR products were subsequently mixed together, before preparing a library for NGS using a nonindexed library adapter.

DNA sequencing reads from each sample were aligned to bisulfite-converted and unconverted versions of the human reference genome (hg18) using Bowtie2. VIM aligned reads were classified as methylated if they indicated that 8 or more CpG dinucleotides were methylated (out of total of 10 CpGs present between the primers in the VIM PCR fragment). CCNA1 aligned reads were classified as methylated if they indicated that 16 or more CpG dinucleotides were methylated (out of a total of 21 CpGs present between the primers in the CCNA1 PCR fragment). These analyses were facilitated by use of Bismark software (30), which was specifically developed for processing bisulfite sequencing data.

Statistical methods

Between-group comparisons of continuous variables were performed using unpaired Student’s t test (for two groups) or one-way analysis of variance (ANOVA) for groups of three or more, followed by the post hoc Student-Newman-Keuls test for all pairwise comparisons. The Mann-Whitney rank sum test was used to determine the P value for comparison of smokers and nonsmokers. Fisher’s exact test was used for comparison of demographic composition of cases/controls in brushing and balloon studies. ROC curves and all associated statistics were generated using MedCalc software. The optimal cutoffs were calculated as maximizing the sum of sensitivity plus specificity.

A test that goes down easy

Barrett's esophagus is a premalignant condition of the distal esophagus that increases the risk of esophageal cancer. Unfortunately, screening for Barrett's esophagus currently requires endoscopy, an invasive and expensive procedure, and thus, it is not routinely performed. Moinova et al. have now demonstrated a simplified approach to screening by identifying a pair of DNA methylation markers that correlate with the presence of Barrett's esophagus. The authors also invented a swallowable balloon-based device that can capture DNA samples for methylation analysis and found that it is well tolerated in patients and provides >90% sensitivity and specificity compared to endoscopy, suggesting its potential as a screening method.
